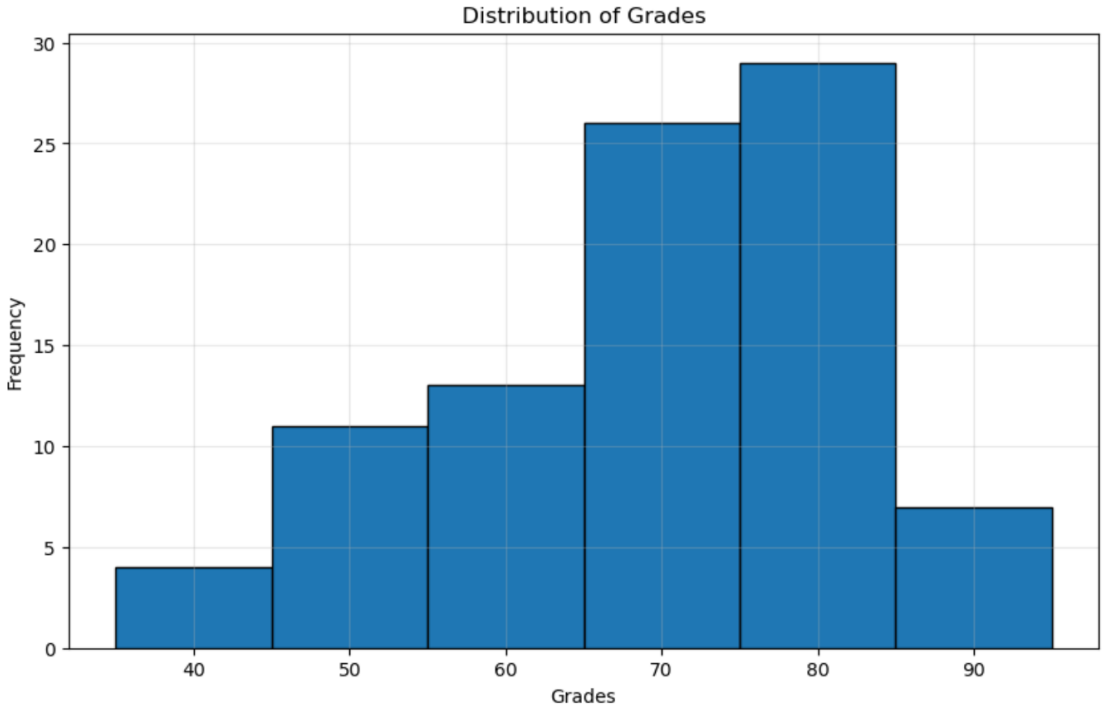
STATS 507
Data Analysis in Python

Week9-2: Pandas

Dr. Xian Zhang

Adapted from slides by Professor Jeffrey Regier

Midterm Stats



Mean: 70.01
Median: 72.50
Maximum: 95.00

Recall Scope of this class

Part 1: Introduction to Python

Data types, functions, classes, objects, functional programming

Part 2: Numerical Computing and Data Visualization

numpy, scipy, matplotlib, scikit-learn

Part 3: Dealing with structured data

pandas, regular expressions, retrieving web data, **SQL**, real datasets

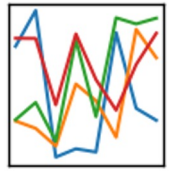
Part4: Intro to Deep Learning

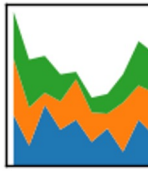
PyTorch, Perceptron, Multi-layer perceptron, SGD, regularization, ConvNets

Pandas

pandas

$$y_{it} = \beta' x_{it} + \mu_i + \epsilon_{it}$$





Yet another **open-sourced**, **practical**, modern data science tool in Python…

- Database-like structures, largely similar to those available in R
- Well integrated with `numpy/scipy`
- Low-level ops implemented in Cython (C+Python=Cython)
- Optimized for most common operations
- E.g., vectorized operations, operations on rows of a table

From the documentation: pandas is a Python package providing fast, flexible, and expressive data structures designed to make working with “relational” or “labeled” data both easy and intuitive. It aims to be the fundamental high-level building block for doing practical, real world data analysis in Python.

https://pandas.pydata.org/

Basic Data Structures

Series: represents a one-dimensional **labeled** array
Labeled just means that there is an **index** into the array
Support vectorized operations

DataFrame: table of rows, with labeled columns
Like a spreadsheet or an R data frame
Support `numpy ufuncs` (provided data are numeric)

1. Pandas Series Basics (creations and properties)

2. Pandas Series Operations

3. Pandas DataFrames

pandas Series Basics

Pandas series are Pandas data structure built on top of NumPy arrays.

- Series also contain a **custom index** and an **optional name**, in addition to the array of data.
- They can be created from other data types, but are usually imported form external sources (csv, Excel or SQL database).
- Two or more Series grouped together form a Pandas DataFrame.

```
1 import pandas as pd
2 import numpy as np
3 numbers = np.random.randn(5)
4 s = pd.Series(numbers)
5 s
```

```
0   -0.318743
1    0.807948
2   -0.216362
3   -0.356014
4    1.542122
dtype: float64
```

- pd is the standard alias for Pandas library
- Pd.series function converts NumPy Arrays into Pandas Series.

pandas Series Creation

Can create a Pandas series from **array-like** structure (e.g., Python list, numpy array, dict).

```
1 import pandas as pd
2 import numpy as np
3 numbers = np.random.randn(5)
4 s = pd.Series(numbers)
5 s
```

```
0   -0.318743
1    0.807948
2   -0.216362
3   -0.356014
4    1.542122
dtype: float64
```

By default, indices are integers, starting from 0, just like you're used to.

pandas tries to infer this data type automatically.

But we can specify a different set of indices if we so choose.

```
1 idx = ['a','b','c','d','e']
2 s = pd.Series(numbers, index=idx)
3 s
```

```
a   -0.318743
b    0.807948
c   -0.216362
d   -0.356014
e    1.542122
dtype: float64
```

Warning: providing too few or too many indices is a ValueError.

`pandas` Series Creation

Can create a `Pandas` series from a **dictionary.**

```
1 d = {'dog':3.1415,'cat':42,'bird':0,'goat':1.618}
2 s = pd.Series(d)
3 s
```

```
bird      0.0000
cat      42.0000
dog       3.1415
goat      1.6180
dtype: float64
```

Can create a series from a dictionary. Keys become indices.

```
1 inds = ['dog','cat','bird','goat','cthulu']
2 s = pd.Series(d, index=inds)
3 s
```

```
dog         3.1415
cat        42.0000
bird        0.0000
goat        1.6180
cthulu         NaN
dtype: float64
```

Index `'cthulu'` doesn't appear in the dictionary, so `pandas` assigns it `NaN`, the standard "missing data" symbol.

`pandas` Series properties

Pandas Series have these key properties:

- **values** – the data array in the Series
- **index** – the index array in the Series
- **name** – the optional name for the Series *(useful for accessing columns in a DataFrame)*
- **dtype** – the data type of the elements in the values array

```
numbers = np.array([2, 50.0, 113.0, 4, 9])
s = pd.Series(numbers, name = "sale")
```

```
# Print out some common and useful attributes
print("\nCommon attributes:")
print(f"Name: {s.name}")
print(f"dtype: {s.dtype}")
print(f"Index: {s.index}")
print(f"Size: {s.size}")
print(f"Shape: {s.shape}")
print(f"Value: {s.values}")
```

```
Common attributes:
Name: sale
dtype: float64
Index: RangeIndex(start=0, stop=5, step=1)
Size: 5
Shape: (5,)
Value: [  2.  50. 113.   4.   9.]
```

1. Pandas Series Basics (creations and properties)

2. Pandas Series Operations

3. Pandas DataFrames

Indexing

Indexing works like you're used to and supports slices, but **not** negative indexing.

```
1 s = pd.Series([2,3,5,7,11])
2 s[0]
```

```
2
```

This object has type `np.int64`

```
1 s[1:3]
```

```
1    3
2    5
dtype: int64
```

This object is another `pandas` Series.

```
1 s[-1]
```

```
---------------------------------------------------------------------------
KeyError                                  Traceback (most recent call last)
<ipython-input-22-0e2107f91cbd> in <module>()
----> 1 s[-1]
```

Indexing

```
1 s = pd.Series([2,3,5,7,11], index=['a','a','a','a','a'])
2 s
```

```
a     2
a     3
a     5
a     7
a    11
dtype: int64
```

Caution: indices need not be unique in `pandas` Series. This will only cause an error if/when you try to perform an operation that requires unique indices.

```
1 s['a']
```

```
a     2
a     3
a     5
a     7
a    11
dtype: int64
```

Slicing and func like Numpy

```
1 s
```

```
dog          3.1415
cat         42.0000
bird         0.0000
goat         1.6180
cthulu          NaN
dtype: float64
```

```
1 s[s>0]
```

```
dog       3.1415
cat      42.0000
goat      1.6180
dtype: float64
```

Series objects are like `np.ndarray` objects, so they support all the same kinds of slice operations, but note that the indices come along with the slices.

Series objects even support most `numpy` functions that act on arrays.

```
1 s**2
```

```
dog           9.869022
cat        1764.000000
bird          0.000000
goat          2.617924
cthulu             NaN
dtype: float64
```

Modifying `Series` like a dictionary

Series objects are `dict`-like, in that we can **access** and **update** entries via their keys.

```
1 s
```

```
dog         3.1415
cat        42.0000
bird        0.0000
goat        1.6180
cthulu         NaN
dtype: float64
```

```
1 s['goat']
```

```
1.6180000000000001
```

```
1 s['cthulu']=-1
2 s
```

```
dog         3.1415
cat        42.0000
bird        0.0000
goat        1.6180
cthulu     -1.0000
dtype: float64
```

Like a dictionary, accessing a non-existent key is a `KeyError`.

```
1 s['penguin']
```

```
---------------------------------
KeyError
<ipython-input-48-a7df9b66ea8a> i
----> 1 s['penguin']
```

Note: I cropped out a bunch of the error message, but you get the idea.

Not shown: Series also support the `in` operator: `x in s` checks if `x` appears as an index of Series `s`. Series also supports the dictionary `get` method.

```
1 s
```

```
dog         3.1415
cat        42.0000
bird        0.0000
goat        1.6180
cthulu     -1.0000
dtype: float64
```

Entries of a Series can be of (almost) any type, and they may be mixed (e.g., some floats, some ints, some strings, etc), but they **CAN NOT be sequences**.

```
1 s['cthulu'] = (1,1)
```

```
---------------------------------
ValueError
<ipython-input-50-47579d9278ca>
----> 1 s['cthulu'] = (1,1)

/Users/keith/anaconda/lib/python2.7/site-packages/pandas
    744                 # GH 6043
    745                 elif _is_scalar_indexer(indexer):
--> 746                     values[indexer] = value
    747
    748                 # if we are an exact match (ex-broad

ValueError: setting an array element with a sequence.
```

More information on indexing: https://pandas.pydata.org/pandas-docs/stable/indexing.html

Universal functions on `Series`

```
1 s
```

```
dog        3.1415
cat            42
bird            0
goat        1.618
cthulu      abcde
dtype: object
```

Series support universal functions, so long as all their entries support operations.

```
1 s + 2*s
```

```
dog                    9.4245
cat                       126
bird                        0
goat                    4.854
cthulu     abcdeabcdeabcde
dtype: object
```

Series operations require that keys be shared. Missing values become `NaN` by default.

```
1 d = {'dog':2,'cat':1.23456}
2 t = pd.Series(d)
3 t
```

```
cat    1.23456
dog    2.00000
dtype: float64
```

```
1 s+t
```

```
bird          NaN
cat       43.2346
cthulu        NaN
dog        5.1415
goat          NaN
dtype: object
```

To reiterate, Series objects support most `numpy` ufuncs. For example, `np.sqrt(s)` is valid, so long as all entries are positive.

Methods

Series have an optional `name` attribute.

After it is set, `name` attribute can be changed with `rename` method.

Note: this returns a new Series. It **does not** change `s.name`.

```
1 s
```

```
bird     0.0000
cat     42.0000
dog      3.1415
goat     1.6180
dtype: float64
```

```
1 s.name = 'aminals'
2 s
```

```
bird     0.0000
cat     42.0000
dog      3.1415
goat     1.6180
Name: aminals, dtype: float64
```

```
1 s.rename('animals')
```

```
bird     0.0000
cat     42.0000
dog      3.1415
goat     1.6180
Name: animals, dtype: float64
```

This will become especially useful when we start talking about DataFrames, because these name attributes will be column names.

Mapping and linking `Series` values

Series `map` method works analogously to Python's `map` function. Takes a function and applies it to every entry.

```
1 s = pd.Series(['dog','goat','skunk'])
2 s
```

```
0       dog
1      goat
2     skunk
dtype: object
```

```
1 s.map(lambda s:len(s))
```

```
0    3
1    4
2    5
dtype: int64
```

Mapping `Series` values

```
1 s = pd.Series(['fruit', 'animal', 'animal', 'fruit', 'fruit'],
2               index=['apple','cat', 'goat','banana','kiwi'])
3 s
```

```
apple      fruit
cat       animal
goat      animal
banana     fruit
kiwi       fruit
dtype: object
```

```
1 t = pd.Series({'fruit':0,'animal':1})
2 s.map(t)
```

```
apple     0
cat       1
goat      1
banana    0
kiwi      0
dtype: int64
```

Series `map` also allows us to change values based on another Series. Here, we're changing the fruit/animal category labels to binary labels.

1. Pandas Series Basics (creations and properties)

2. Pandas Series Operations

3. Pandas DataFrames

`pandas` DataFrames

Fundamental unit of `pandas`

- Analogous to R data frame

2-dimensional structure (i.e., rows and columns)

- Columns, of potentially different types
- Think: spreadsheet (or, better, database)

Can be created from many different objects

- Dict of {ndarrays, Python lists, dicts, Series}
- 2-dimensional ndarray
- Series

Creation

Creating a DataFrame from a dictionary, the keys become the column names. Values become the columns of the dictionary.

```
1 d = {'A':pd.Series([1,2,3], index=['cat','dog','bird']),
2      'B':{'cat':3.14, 'dog':2.718, 'bird':1.618, 'goat':0.5772}}
3 df = pd.DataFrame(d)
4 df
```

	A	B
bird	3.0	1.6180
cat	1.0	3.1400
dog	2.0	2.7180
goat	NaN	0.5772

Each column may have its own indices, but the resulting DataFrame will have a row for every index (i.e., every row name) that appears.

Indices that are unspecified for a given column receive `NaN`.

Note: in the code above, we specified the two columns differently. One was specified as a Series object, and the other as a dictionary. This is just to make the point that there is flexibility in how you construct your DataFrame. More options: https://pandas.pydata.org/pandas-docs/stable/generated/pandas.DataFrame.html

Creation

Dictionary has 4 keys, so 4 columns.

```
1 d = {'Undergrad' : pd.Series(['UMich', 'Stanford', 'Princeton', 'Columbia'],
2                               index=['Ford', 'Hoover', 'Wilson', 'Obama']),
3      'PhD' : {'Wilson':'Johns Hopkins'},
4      'JD' : {'Ford':'Yale','Obama':'Harvard'},
5      'Terms': pd.Series([1,1,2,2], index=['Ford', 'Hoover', 'Wilson', 'Obama']) }
6 presidents = pd.DataFrame(d)
7 presidents
```

Note: Dictionary includes both text and numeric columns

	JD	PhD	Terms	Undergrad
Ford	Yale	NaN	1	UMich
Hoover	NaN	NaN	1	Stanford
Obama	Harvard	NaN	2	Columbia
Wilson	NaN	Johns Hopkins	2	Princeton

By default, rows and columns are ordered alphabetically.

row/column as attributes

	JD	PhD	Terms	Undergrad
Ford	Yale	NaN	1	UMich
Hoover	NaN	NaN	1	Stanford
Obama	Harvard	NaN	2	Columbia
Wilson	NaN	Johns Hopkins	2	Princeton

```
1 presidents.columns
```

```
Index([u'JD', u'PhD', u'Terms', u'Undergrad'], dtype='object')
```

```
1 presidents.index
```

```
Index([u'Ford', u'Hoover', u'Obama', u'Wilson'], dtype='object')
```

Row and column names accessible as the `index` and column `attributes`, respectively, of the DataFrame.

Both are returned as `pandas` Index objects.

Accessing/adding columns

```
1 presidents['PhD']
```

```
Ford                    NaN
Hoover                  NaN
Obama                   NaN
Wilson     Johns Hopkins
Name: PhD, dtype: object
```

DataFrame acts like a dictionary whose keys are column names, values are Series.

```
1 type(presidents['PhD'])
```

```
pandas.core.series.Series
```

```
1 presidents['Years'] = 4*presidents['Terms']
2 presidents
```

	JD	PhD	Terms	Undergrad	Years
Ford	Yale	NaN	1	UMich	4
Hoover	NaN	NaN	1	Stanford	4
Obama	Harvard	NaN	2	Columbia	8
Wilson	NaN	Johns Hopkins	2	Princeton	8

Like a dictionary, we can create new key-value pairs.

Note: factually, this isn't quite correct, because Ford did not serve a full term. https://en.wikipedia.org/wiki/Gerald_Ford

Adding columns

	JD	PhD	Terms	Undergrad	Years
Ford	Yale	NaN	1	UMich	4
Hoover	NaN	NaN	1	Stanford	4
Obama	Harvard	NaN	2	Columbia	8
Wilson	NaN	Johns Hopkins	2	Princeton	8

```
1 presidents['Nobels'] = [0,0,1,1]
2 presidents
```

Since the row labels are ordered, we can specify a new column directly from a Python list, `numpy` array, etc. without having to specify indices.

	JD	PhD	Terms	Undergrad	Years	Nobels
Ford	Yale	NaN	1	UMich	4	0
Hoover	NaN	NaN	1	Stanford	4	0
Obama	Harvard	NaN	2	Columbia	8	1
Wilson	NaN	Johns Hopkins	2	Princeton	8	1

Note: by default, new column are inserted at the end. See the `insert` method to change this behavior: https://pandas.pydata.org/pandas-docs/stable/generated/pandas.DataFrame.insert.html

Adding columns

	JD	PhD	Terms	Undergrad	Nobels	Years
Ford	Yale	NaN	1	UMich	0	4
Hoover	NaN	NaN	1	Stanford	0	4
Obama	Harvard	NaN	2	Columbia	1	8
Wilson	NaN	Johns Hopkins	2	Princeton	1	8

```
1 presidents['Fields Medals'] = 0
2 presidents
```

Scalars are broadcast across the rows.

	JD	PhD	Terms	Undergrad	Nobels	Years	Fields Medals
Ford	Yale	NaN	1	UMich	0	4	0
Hoover	NaN	NaN	1	Stanford	0	4	0
Obama	Harvard	NaN	2	Columbia	1	8	0
Wilson	NaN	Johns Hopkins	2	Princeton	1	8	0

Deleting columns

	JD	PhD	Terms	Undergrad	Nobels	Years	Fields Medals
Ford	Yale	NaN	1	UMich	0	4	0
Hoover	NaN	NaN	1	Stanford	0	4	0
Obama	Harvard	NaN	2	Columbia	1	8	0
Wilson	NaN	Johns Hopkins	2	Princeton	1	8	0

```
1 del presidents['Years']
2 presidents
```

Delete columns identically to deleting keys from a dictionary. One can use the `del` keyword, or pop a key.

	JD	PhD	Terms	Undergrad	Nobels	Fields Medals
Ford	Yale	NaN	1	UMich	0	0
Hoover	NaN	NaN	1	Stanford	0	0
Obama	Harvard	NaN	2	Columbia	1	0
Wilson	NaN	Johns Hopkins	2	Princeton	1	0

```
1 fields = presidents.pop('Fields Medals')
```

Indexing & Selection

Select columns by their names.

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1
Wilson	NaN	Johns Hopkins	2	Princeton	1

```
1 presidents['JD']
```

```
Ford          Yale
Hoover         NaN
Obama      Harvard
Wilson         NaN
Name: JD, dtype: object
```

```
1 presidents.loc['Obama']
```

```
JD             Harvard
PhD                NaN
Terms                2
Undergrad     Columbia
Nobels               1
Name: Obama, dtype: object
```

```
1 presidents[1:3]
```

`df.loc` selects rows by their labels.
`df.iloc` selects rows by their integer labels (starting from 0).

	erms	Undergrad	Nobels
	1	Stanford	0
	2	Columbia	1

```
1 presidents.iloc[1]
```

```
JD                NaN
PhD               NaN
Terms               1
Undergrad    Stanford
Nobels               0
Name: Hoover, dtype: object
```

```
1 presidents[presidents['Terms']<2]
```

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1
Wilson	NaN	Johns Hopkins	2	Princeton	1

```
1 presidents
```

```
JD
PhD
Terms
Undergrad     Columbia
Nobels
Name: Obama, d
```

```
1 presidents
```

```
JD                  NaN
PhD                 NaN
Terms                 1
Undergrad      Stanford
Nobels                0
Name: Hoover, dtype: object
```

Select rows by their numerical indices (again 0-indexed). This supports slices.

Note: one can also select slices with lists of column names, e.g., `presidents[['JD','PhD']]`.

```
1 presidents['JD']
```

```
Ford          Yale
Hoover         NaN
Obama      Harvard
Wilson         NaN
Name: JD, dtype: object
```

```
1 presidents[1:3]
```

	JD	PhD	Terms	Undergrad	Nobels
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1

```
1 presidents[presidents['Terms']<2]
```

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0

Indexing and selection

	JD	PhD	Terms	Undergrad	Nobels
Ford	Yale	NaN	1	UMich	0
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1
Wilson	NaN	Johns Hopkins	2	Princeton	1

```
1 presidents.loc['Obama']
```

```
JD              Harvard
PhD                 NaN
Terms                 2
Undergrad      Columbia
Nobels                1
Name: Obama, dtype: object
```

```
1 presidents.iloc[1]
```

```
JD                 NaN
PhD                NaN
Terms                1
Undergrad     Stanford
Nobels               0
Name: Hoover, dtype: object
```

Select rows by Boolean expression.

```
1 presidents['JD']
```

```
Ford          Yale
Hoover         NaN
Obama      Harvard
Wilson         NaN
Name: JD, dtype: object
```

```
1 presidents[1:3]
```

	JD	PhD	Terms	Undergrad	Nobels
Hoover	NaN	NaN	1	Stanford	0
Obama	Harvard	NaN	2	Columbia	1

More on indexing:
https://pandas.pydata.org/pandas-docs/stable/indexing.html

Arithmetic

```
1 df1 = pd.DataFrame(np.random.randn(8, 4), columns=['A', 'B', 'C', 'D'])
2 df2 = pd.DataFrame(np.random.randn(5, 3), columns=['A', 'B', 'C'])
3 df1+df2
```

	A	B	C	D
0	0.722814	-1.889204	-1.170304	NaN
1	1.370720	-1.033425	-0.719628	NaN
2	-2.281526	0.899515	-0.298246	NaN
3	-4.276271	-2.327304	-0.444528	NaN
4	-1.418512	0.463528	0.428446	NaN
5	NaN	NaN	NaN	NaN
6	NaN	NaN	NaN	NaN
7	NaN	NaN	NaN	NaN

`pandas` tries to align the DataFrames as best it can, filling in non-alignable entries with NaN.

In this example, rows 0 through 4 and columns A through C exist in both DataFrames, so these entries can be successfully added. All other entries get NaN, because `x + NaN = NaN`.

Arithmetic

```
1 df = pd.DataFrame(np.random.randn(4, 2), columns=['A', 'B'])
2 df
```

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

By default, Series are aligned to DataFrames via row-wise broadcasting.

```
1 df - df.iloc[0]
```

`df.iloc[0]` is a Series representing the 0-th row of `df`. When we try to subtract it from `df`, `pandas` forces dimensions to agree by broadcasting the operation across all rows of `df`.

	A	B
0	0.000000	0.000000
1	2.442791	0.794009
2	0.661785	0.957734
3	1.548277	-0.136072

Arithmetic

```
1 df
```

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

Scalar addition and multiplication works in the obvious way. DataFrames also support scalar division, exponentiation… Basically every `numpy` ufunc.

```
1 10*df + 1
```

	A	B
0	-12.316346	-4.008702
1	12.111569	3.931385
2	-5.698497	5.568633
3	3.166428	-5.369423

DataFrames also support entrywise Boolean operations.

```
1 df > 0
```

	A	B
0	False	False
1	True	True
2	False	True
3	True	False

Arithmetic with DataFrames

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

`pandas` DataFrames support `numpy`-like any and all methods.

```
1 (df > 0).any()
```

```
A     True
B     True
dtype: bool
```

```
1 (df > 0).all()
```

```
A     False
B     False
dtype: bool
```

Just like `numpy`, direct Boolean operations are not supported.

```
1 df or df
```

```
---------------------
ValueError
```

```
ValueError: The truth value of a
    DataFrame is ambiguous.
    Use a.empty, a.bool(), a.item(),
        a.any() or a.all().
```

Arithmetic with DataFrames

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

```
1 df.values
```

```
array([[-1.33163456, -0.50087024],
       [ 1.11115689,  0.29313846],
       [-0.66984966,  0.45686335],
       [ 0.21664278, -0.63694229]])
```

`values` attribute stores the entries of the table in a numpy array. This is occasionally useful when you want to stop dragging the extra information around and just work with the numbers in the table.

Arithmetic with DataFrames

```
1 df
```

	A	B
0	-1.331635	-0.500870
1	1.111157	0.293138
2	-0.669850	0.456863
3	0.216643	-0.636942

DataFrames support entrywise multiplication. The `T` attribute is the transpose of the DataFrame.

```
df.T*df.T
```

	0	1	2	3
A	1.773251	1.23467	0.448699	0.046934
B	0.250871	0.08593	0.208724	0.405695

DataFrames also support matrix multiplication via the `numpy`-like `dot` method. The DataFrame dimensions must be conformal, of course.

```
df.T.dot(df)
```

	A	B
A	3.503553	0.548680
B	0.548680	0.951221

Note: Series also support a `dot` method, so you can compute inner products.

Removing NaNs

	A	B	C	D
0	-9.422331	1.100197	8.034010	NaN
1	-1.520140	5.655382	-1.692761	NaN
2	0.399654	10.058568	0.502007	NaN
3	-4.070947	2.237868	10.530079	NaN
4	1.603739	8.255591	1.892258	NaN
5	1.123450	3.141590	NaN	NaN

DataFrame `dropna` method removes rows or columns that contain NaNs.

`axis` argument controls whether we act on rows, columns, etc.

`how='any'` will remove all rows/columns that contain even one NaN. `how='all'` removes rows/columns that have all entries NaN.

```
1 df.dropna(axis=1,how='any')
```

	A	B
0	-9.422331	1.100197
1	-1.520140	5.655382
2	0.399654	10.058568
3	-4.070947	2.237868
4	1.603739	8.255591
5	1.123450	3.141590

```
1 df.dropna(axis=1,how='all')
```

	A	B	C
0	-9.422331	1.100197	8.034010
1	-1.520140	5.655382	-1.692761
2	0.399654	10.058568	0.502007
3	-4.070947	2.237868	10.530079
4	1.603739	8.255591	1.892258
5	1.123450	3.141590	NaN

Reading/writing files

`pandas` supports read/write for a wide range of different file formats. This flexibility is a major advantage of `pandas`.

Format Type	Data Description	Reader	Writer
text	CSV	read_csv	to_csv
text	JSON	read_json	to_json
text	HTML	read_html	to_html
text	Local clipboard	read_clipboard	to_clipboard
binary	MS Excel	read_excel	to_excel
binary	HDF5 Format	read_hdf	to_hdf
binary	Feather Format	read_feather	to_feather
binary	Parquet Format	read_parquet	to_parquet
binary	Msgpack	read_msgpack	to_msgpack
binary	Stata	read_stata	to_stata
binary	SAS	read_sas	
binary	Python Pickle Format	read_pickle	to_pickle
SQL	SQL	read_sql	to_sql
SQL	Google Big Query	read_gbq	to_gbq

https://pandas.pydata.org/pandas-docs/stable/io.html

Reading/writing files

`pandas` supports read/write for a wide range of different file formats. This flexibility is a major advantage of `pandas`.

Format Type	Data Description	Reader	Writer

binary	Stata		
binary	SAS		
binary	Python Pickle Form		
SQL	SQL		
SQL	Google Big Query	read_gbq	to_gbq

`pandas` file I/O is largely similar to R `read.table` and similar functions, so I'll leave it to you to read the `pandas` documentation as needed.

Table credit: https://pandas.pydata.org/pandas-docs/stable/io.html

Summarizing DataFrames

`pd.read_csv()` reads a comma-separated file into a DataFrame.

`info()` method prints summary data about the DataFrame. Number of rows, column names and their types, etc.

Note: there is a separate `to_string()` method that generates a string representing the DataFrame in tabular form, but this usually doesn't display well if you have many columns.

```
1 baseball = pd.read_csv('baseball.csv')
2 baseball.info()
```

```
<class 'pandas.core.frame.DataFrame'>
Int64Index: 21699 entries, 4 to 89534
Data columns (total 22 columns):
id        21699 non-null object
year      21699 non-null int64
stint     21699 non-null int64
team      21699 non-null object
lg        21634 non-null object
g         21699 non-null int64
ab        21699 non-null int64
r         21699 non-null int64
h         21699 non-null int64
X2b       21699 non-null int64
X3b       21699 non-null int64
hr        21699 non-null int64
rbi       21687 non-null float64

cs        17174 non-null float64
bb        21699 non-null int64
so        20394 non-null float64
ibb       14171 non-null float64
hbp       21322 non-null float64
sh        20739 non-null float64
sf        14309 non-null float64
gidp      16427 non-null float64
dtypes: float64(9), int64(10), object(3)
memory usage: 3.8+ MB
```

Summarizing DataFrames

`head()` method displays just the first few rows of the DataFrame (5 by default; change this by supplying an argument). `tail()` displays the last few rows.

```
1 baseball.head()
```

	id	year	stint	team	lg	g	ab	r	h	X2b	...	rbi	sb	cs	bb	so	ibb	hbp	sh	sf	gidp
4	ansonca01	1871	1	RC1	NaN	25	120	29	39	11	...	16.0	6.0	2.0	2	1.0	NaN	NaN	NaN	NaN	NaN

5 rows × 22 columns

Note: R and pandas both supply `head`/`tail` functions, named after UNIX/Linux commands that displays the first/last lines of a file.

Comparing DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

These two DataFrames *ought* to be equivalent...

```
1 df1 = 2*df
2 df2 = df+df
3 (df1==df2).all()
```

...but they aren't.

```
A    False
B    False
C    False
D    False
dtype: bool
```

```
1 np.nan == np.nan
```

```
False
```

```
1 df1.equals(df2)
```

```
True
```

Comparing DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

These two DataFrames *ought* to be equivalent...

```
1 df1 = 2*df
2 df2 = df+df
3 (df1==df2).all()
```

```
A    False
B    False
C    False
D    False
dtype: bool
```

...but they aren't.

The problem comes from the fact that NaNs are not equal to one another.

```
1 np.nan == np.nan
```

```
False
```

Solution: DataFrames have a separate `equals()` method for checking the kind of equality that we meant above.

```
1 df1.equals(df2)
```

```
True
```

Comparing DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

There is a solid design principle behind this. If there are NaNs in our data, we want to err on the side of being overly careful about what operations we perform on them. We see similar ideas in `numpy` and in R.

```
1 df1 = 2*df
2 df2 = df+df
3 (df1==df2).all()
```

```
A    False
B    False
C    False
D    False
dtype: bool
```

Solution: DataFrames have a separate `equals()` method for checking the kind of equality that we meant above.

```
1 np.nan == np.nan
```

```
False
```

```
1 df1.equals(df2)
```

```
True
```

Statistical Operations on DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

Getting means of DataFrame rows/columns using numpy is possible, but tedious.

```
1 np.nanmean(np.array(df.iloc[1]))
```

```
-0.50977640954057268
```

`DataFrame.mean` method is a cleaner way to do the same thing. Argument picks out values across which axis to take means on: rows (0) or columns (1).

```
1 df.mean(0)
```

```
A   -4.706220
B   -3.109512
C   -1.763407
D          NaN
dtype: float64
```

```
1 df.mean(1)
```

```
0   -3.115592
1   -0.509776
2   -2.240343
3   -9.397471
4   -0.702050
5          NaN
dtype: float64
```

Statistical Operations on DataFrames

	A	B	C	D
0	2.			
1	5.			
2	-9.			
3	-17.			
4	-5.			
5				

Of course, DataFrames also support a bunch of related functions, that work similarly: `sum`, `min`, `max`, `std`, `var` etc. All of these functions take an optional Boolean argument `skipna`. If `True`, NaNs are **not included** in the computation. If `False`, NaNs are included (which can mean either that the computation doesn't work at all, or changes the value only slightly). More information: https://pandas.pydata.org/pandas-docs/stable/user_guide/basics.html#descriptive-statistics

```
1  np.nanmean(np.array(df.iloc[1]))
```

```
-0.50977640954057268
```

`DataFrame.mean` method is a cleaner way to do the same thing. Argument picks out which axis to take means on: rows (1) or columns (0).

```
1  df.mean(0)
```

```
A   -4.706220
B   -3.109512
C   -1.763407
D         NaN
dtype: float64
```

```
1  df.mean(1)
```

```
0   -3.115592
1   -0.509776
2   -2.240343
3   -9.397471
4   -0.702050
5         NaN
dtype: float64
```

Summarizing DataFrames

	A	B	C	D
0	2.891255	-7.556816	-4.681215	NaN
1	5.482881	-4.133700	-2.878510	NaN
2	-9.126106	3.598060	-1.192984	NaN
3	-17.105085	-9.309218	-1.778110	NaN
4	-5.674048	1.854114	1.713784	NaN
5	NaN	NaN	NaN	NaN

`DataFrame.describe()` is similar to the R `summary()` function. Non-numeric data will get statistics like counts, mean, std, etc. If a DataFrame has mixed types (both numeric and non-numeric), the non-numeric data is excluded by default.

```
df.describe()
```

	A	B	C	D
count	5.000000	5.000000	5.000000	0.0
mean	-4.706220	-3.109512	-1.763407	NaN
std	9.161650	5.676551	2.354438	NaN
min	-17.105085	-9.309218	-4.681215	NaN
25%	-9.126106	-7.556816	-2.878510	NaN
50%	-5.674048	-4.133700	-1.778110	NaN
75%	2.891255	1.854114	-1.192984	NaN
max	5.482881	3.598060	1.713784	NaN

Details and optional arguments:
https://pandas.pydata.org/pandas-docs/stable/basics.html#summarizing-data-describe

Row- and column-wise functions: `apply()`

	A	B	C	D
0	1.284355	1.073402	0.297575	NaN
1	-0.791592	0.841969	0.509262	NaN
2	-0.657900	-2.184139	1.635736	NaN
3	-1.897574	0.502787	-1.911790	NaN
4	0.592821	2.091333	-2.813032	NaN
5	NaN	NaN	NaN	NaN

`DataFrame.apply()` takes a function and applies it to each column of the DataFrame.

```
In [1]: df.apply(np.mean)
```

```
A   -0.293978
B    0.465070
C   -0.456450
D         NaN
dtype: float64
```

`Axis` argument is 0 by default (across all rows ie., column values). Change to 1 for across columns ie., row values.

```
In [1]: df.apply(np.mean, axis=1)
```

```
0    0.885111
1    0.186546
2   -0.402101
3   -1.102192
4   -0.042959
5         NaN
dtype: float64
```

Row- and column-wise functions: `apply()`

	A	B	C
0	0.938898	2.047553	-0.525091
1	1.066293	-0.599466	-0.195606
2	-0.939341	0.022376	1.453082
3	1.114664	-0.408026	-0.811081
4	2.257680	0.280994	0.847329

```
1 def quadratic(x, a, b, c=1):
2     return a*x**2 + b*x + c
3 df.apply(quadratic, args=(1,2), c=5)
```

We can pass positional and keyword arguments into the function via `df.apply`. Args is a tuple of the positional arguments (in order), followed by the keyword arguments.

	A	B	C
0	7.759325	13.287581	4.225538
1	8.269566	4.160428	4.647050
2	4.003679	5.045253	10.017612
3	8.471805	4.350433	4.035691
4	14.612481	5.640946	7.412624

Note: "apply() takes an argument `raw` which is `False` by default, which converts each row or column into a Series before applying the function. When set to `True`, the passed function will instead receive an ndarray object, which has positive performance implications if you do not need the indexing functionality." This can be useful if your function is meant to work specifically with Series.

Element-wise function application

`applymap` works similarly to Python's `map` function (and the Series `map` method). Applies its argument function to every entry of the DataFrame.

	A	B
0	cat	unicorn
1	dog	chupacabra
2	bird	pixie

```
df.applymap(lambda s:s.upper())
```

	A	B
0	CAT	UNICORN
1	DOG	CHUPACABRA
2	BIRD	PIXIE
